Does p-type ohmic contact exist in WSe<sub>2</sub>–metal interfaces?

Yangyang Wang,‡a,b Ruoxi Yang,‡a,c Ruge Quhe,‡a,d,e Hongxia Zhong,‡a,f Linxiao Cong,a Meng Ye,a Zeyuan Ni,a Zhigang Song,a Jinbo Yang,a–g Junjie Shi,a Ju Li,b and Jing Lu*a,g

Formation of low-resistance metal contacts is the biggest challenge that masks the intrinsic exceptional electronic properties of two dimensional WSe<sub>2</sub> devices. We present the first comparative study of the interfacial properties between monolayer/bilayer (ML/BL) WSe<sub>2</sub> and Sc, Al, Ag, Au, Pd, and Pt contacts by using {	extit{ab initio}} energy band calculations with inclusion of the spin–orbital coupling (SOC) effects and quantum transport simulations. The interlayer coupling tends to reduce both the electron and hole Schottky barrier heights (SBHs) and alters the polarity for the WSe<sub>2</sub>–Au contact, while the SOC chiefly reduces the hole SBH. In the absence of the SOC, the Pd contact has the smallest hole SBH. Dramatically, the Pt contact surpasses the Pd contact and becomes the p-type ohmic or quasi-ohmic contact with inclusion of the SOC. Therefore, p-type ohmic or quasi-ohmic contact exists in WSe<sub>2</sub>–metal interfaces. Our study provides a theoretical foundation for the selection of favorable metal electrodes in ML/BL WSe<sub>2</sub> devices.

Introduction

Two dimensional (2D) transition-metal dichalcogenides (TMDs) are attracting much recent attention because they have a wide range of application prospects in electronics, photoelectronics, and valleytronics. Among 2D TMDs, monolayer (ML) and bilayer (BL) MoS<sub>2</sub> and WSe<sub>2</sub> are probably the most intensively studied. 2D WSe<sub>2</sub> distinguishes itself from 2D MoS<sub>2</sub> mainly in two aspects: (1) 2D WSe<sub>2</sub> has a much enhanced spin–orbit coupling (SOC) due to the heavier W and Se atoms. For example, the splitting of the valence band maximum (VBM) is about 0.15 eV in ML MoS<sub>2</sub> but is enhanced to 0.46 eV in ML WSe<sub>2</sub>. Therefore, 2D WSe<sub>2</sub> is more suitable for the spintronics purpose. (2) 2D MoS<sub>2</sub> favors n-type doping, whereas 2D WSe<sub>2</sub> prefers p-type doping as a result of much higher positions of the conduction band minimum (CBM) and the VBM.

A device often needs a contact with metal electrodes, and the formation of low-resistance metal contacts is the biggest challenge that masks the intrinsic exceptional electronic properties of 2D TMDs. In the absence of a controllable and sustainable substitutional doping scheme, one has to rely on the work function of contact metals to inject appropriate types of carriers into the respective bands of 2D TMDs. Such metal–semiconductor contacts are often associated with a formation of a finite Schottky barrier, which decreases the carrier injection efficiency. Apparently, decreasing Schottky barrier height (SBH) is critical to reach a high performance of the device, and a low resistance ohmic contact with vanishing SBH is highly desirable. Unfortunately, the SBH does not simply depend on the difference between the intrinsic Fermi level ($E_f$) of a metal and the CBM or VBM of the semiconductor due to the...
complex Fermi level pinning, which renders the appearance of ohmic contact rather difficult.\textsuperscript{24,25}

There have been a lot of research studies on 2D MoS\(_2\)-metal interfaces.\textsuperscript{21,26–31} However, in terms of recent reports the Fermi level of elemental metals is pinned close to the conduction band of MoS\(_2\), and no n-type low-resistance ohmic contact has been revealed either experimentally or theoretically in 2D MoS\(_2\) even with low work function metals such as Ti and Sc.\textsuperscript{3,13,21,24,32} Inserting a monolayer h-BN can break the interface interaction between metal and MoS\(_2\), thus efficiently lowering the Fermi level pinning and attain vanishing n-type SBHs based on the density functional calculations.\textsuperscript{33} Ni-etched graphene has been proved experimentally as an effective buffer layer to reduce the n-type contact resistance of MoS\(_2\)-Ni.\textsuperscript{34} To achieve efficient hole contacts experimentally, molybdenum trioxide (MoO\(_3\), \(x < 3\))\textsuperscript{35,36} is used as a buffer layer between the metal and MoS\(_2\) and shows the unambiguous advantages of hole injections over the conventionally explored metal contacts, mainly due to their high work functions and the relatively weak Fermi level pinning at the interfaces. The utilization of graphene oxide\textsuperscript{37} was also proposed and demonstrated as a promising hole injection layer by using first-principles computations.

Compared with those about MoS\(_2\), the studies of 2D WSe\(_2\)-metal interfaces are more limited. In the experimental aspect, Javey et al.’s measurement showed that high work function Pd forms the lowest resistance to the valence band of ML WSe\(_2\) for hole transport, while lower function Ag, Ni, Au, Ti, and Gd have high SBH to both the valence band and the conduction band of ML WSe\(_2\).\textsuperscript{5} Banerjee et al. claimed that Al forms a n-type Schottky contact with ML WSe\(_2\), but Ti, In, and Ag form n-type ohmic contacts according to their measured output linear characteristics.\textsuperscript{4} In the theoretical aspect, the Schottky barrier is always present in ML WSe\(_2\) and In, Ti, Al, Au, and Pd interfaces, where the SOC is not considered in the energy band calculations.\textsuperscript{4,21} Three fundamental issues arise: (1) which elemental metal has the smallest hole SBH when contacted with WSe\(_2\)? (2) Whether p-type ohmic contact is present in ML WSe\(_2\)-metal contacts? (3) What are the effects of the SOC on the SBH of ML WSe\(_2\)-metal contacts? The SBH depends on the difference between \(E_\Gamma\) of the metal electrode and the band edge of the channel semiconductor in a device environment. Given a rise of 0.23 eV of the VBM due to the SOC splitting in ML WSe\(_2\),\textsuperscript{3} the ignoring of it in determining the hole SBH appears rather unacceptable unless there is the existence of a full Fermi level pinning during the SOC process.

Due to the strong interlayer coupling, BL WSe\(_2\) has a reduced band gap compared with the ML one (1.44 eV vs. 1.67 eV at the density functional theory (DFT) level).\textsuperscript{38} Therefore, a reduced SBH and thus a higher carrier injection efficiency can be expected in BL WSe\(_2\)-metal contacts, suggesting a better device performance of BL WSe\(_2\) as the channel compared with ML WSe\(_2\) given the identical gate voltage controllability. However, to the best of our knowledge, the interfacial properties of BL WSe\(_2\)-metal contacts have not been investigated.

In this article, we provide a comparative study of the interfacial properties of ML and BL WSe\(_2\) on several commonly used metals (Sc, Al, Ag, Au, Pd, and Pt), for the first time by using the DFT energy band calculation with inclusion of the SOC effects. We find that the interlayer coupling decreases both the electron and hole SBHs and even alters the polarity of the WSe\(_2\)-Au contact. No ohmic contact is revealed in the absence of the SOC, and the Pd contact has the minimum hole SBH (0.22/0.27 eV for the ML/BL WSe\(_2\) case). However, when the SOC is included, ML and BL WSe\(_2\)-Pt interfaces dramatically have the minimum hole SBHs and actually become p-type ohmic or quasi-ohmic contacts. A more reliable approach to treat the SBH is \textit{ab initio} quantum transport simulation based on a two-probe model, which is also performed and gives a hole SBH similar to that of the energy band calculation for the ML WSe\(_2\)-Pt interface in the absence of the SOC.

**Computational methods**

The geometry optimizations are carried out by employing the CASTEP package\textsuperscript{39} with the ultrasoft pseudopotential\textsuperscript{40} and plane-wave basis set. The cut-off energy is 400 eV. To take the dispersion interaction into account, a DFT-D semiempirical dispersion-correction approach is used with the Ortmann–Bechstedt–Schmidt (OBS) scheme.\textsuperscript{41} The dipole correction to the total energies is adopted. The stopping criteria for the ionic relaxation are such that the remnant force on each atom is below 0.01 eV Å\(^{-1}\) and that energies are converged to within 10\(^{-5}\) eV per atom. The electronic structures are calculated with the projector-augmented wave (PAW) pseudopotential\textsuperscript{42,43} and plane-wave basis set with a cut-off energy of 400 eV implemented in the Vienna \textit{ab initio} simulation package (VASP) in order to analyze the band components.\textsuperscript{44–47} The Monkhorst–Pack\textsuperscript{48} k-point mesh is sampled with a separation of about 0.10 and 0.03 Å\(^{-1}\) in the Brillouin zone during the relaxation and electronic calculation periods, respectively. Our tests show that the band structures generated from CASTEP and VASP packages coincide well.

The WSe\(_2\) transistor is simulated using the DFT coupled with the non-equilibrium Green's function (NEGF) method, as implemented in the ATK 11.8 package.\textsuperscript{46,47} The single-zeta plus polarization (SZP) basis set is used. The Monkhorst–Pack k-point meshes for the central region and electrodes are sampled with \(1 \times 50 \times 1\) and \(50 \times 50 \times 1\) separately. The temperature is set to 300 K. The Neumann condition is used on the boundaries of the direction vertical to the WSe\(_2\) plane. On the surfaces connecting the electrodes and the central region, we employ the Dirichlet boundary condition to ensure the charge neutrality in the source and the drain region. The transmission coefficient at energy \(E\) averaged over 50 \(k_y\)-points perpendicular to the transport direction (\(x\) direction) is obtained by

\[
T(E) = \text{Tr}[G'\Gamma_L(E)G\Gamma_R(E)]
\]

where \(G'^{(a)}\) is the retarded (advanced) Green function and \(\Gamma_{L(R)}(E) = i\left(\Sigma_{L(R)} - \Sigma_{L(R)}^\prime\right)\) is the level broadening due to the
left (right) electrode expressed in terms of the electrode self-energy $\sum_{\text{ele}}$. Throughout the paper, the generalized gradient approximation (GGA) functional to the exchange-correction functional of the Perdew–Wang 91 (PW91) form$^{9}$ is adopted.

Results and discussion

Interface modeling and stability

We use six layers of metal atoms (Sc in (0001) orientation and Al, Ag, Au, Pd and Pt in (111) orientation) to model the metal surface because 6-layer metal atoms can give converged properties of the contact system according to the convergence tests done in the previous studies$^{21,27}$ and ours. The calculated in-plane lattice constant of WSe$_2$ is $a = 3.29 \, \text{Å}$, in good agreement with the experimental value.$^{50}$ As the properties of WSe$_2$ are sensitive to its lattice parameter, we fix the lattice constant of WSe$_2$ to its optimized value and adjust the metal lattice to be commensurable to the WSe$_2$ lattice. The $(1 \times 1)$ unit cell of the Sc (0001) face is adjusted to the $(1 \times 1)$ unit cell of WSe$_2$, and the $(2 \times 2)$ unit cells of Al, Ag, Au, Pd and Pt (111) faces are adjusted to the $(\sqrt{3} \times \sqrt{3})$ R30$^\circ$ unit cell of WSe$_2$. The lattice mismatch in each metal is listed in Table 1, ranging from 0.91%–3.19%. The in-plane lattice constant of the supercell is fixed during the relaxation. A vacuum buffer space of at least 20 Å is set to avoid spurious interaction between periodic images. The most stable ML WSe$_2$–metal contact geometries are obtained by optimizing the structures from different initial configurations. The initial configurations of BL WSe$_2$–metal interfaces are constructed in terms of AA’ stacking in WSe$_2$ (a $D_{\text{h}}$ point group symmetry)$^{51}$ on the basis of the most stable ML WSe$_2$–metal interface configurations.

The most stable configurations of the ML WSe$_2$–metal interfaces are shown in Fig. 1. The relative positions between ML WSe$_2$ and metal substrates along the interface directions are different for different metals. On the Sc(0001) surface, the W atoms in the primitive cell sit above the top metal atoms, and

![Fig. 1](https://example.com/fig1.png)

**Table 1** Calculated interfacial properties of ML and BL WSe$_2$ on the metal surfaces. $\alpha_{\text{exc}}^\text{exp}$ represents the experimental cell parameters of the surface unit cells shown in Fig. 1 for various metals, with lattice mismatch in percentage given below in parenthesis. The equilibrium distance $d_z$ is the averaged distance between the surface Se atoms of WSe$_2$ and the relaxed positions of the topmost metal layer in the z direction. $E_b$ is the binding energy per surface W atom between WSe$_2$ and a given metal. $W_a$ and $W$ are the calculated work functions for the clean metal surface and WSe$_2$–metal contact, respectively. The SBHs obtained from band calculation with (without) inclusion of the SOC, transport simulation without inclusion of the SOC, and obtained in the previous work without inclusion of the SOC are given for comparison. Electron SBH is given for the n-type Schottky barrier and hole SBH is given for the p-type Schottky barrier. The Schottky barrier is always formed at the vertical direction except for the Sc surface.

the Se atoms sit above the second layer metal atoms (Fig. 1c); on the Al and Pt (111) surfaces, the W atoms in the supercell are all above the centers of the triangles formed by the fcc, hcp, and top sites, and the three pairs of Se atoms sit above the fcc, hcp, and top sites, respectively (Fig. 1d); on Pd (111), the three W atoms in the supercell sit above the fcc, hcp, and top sites, respectively, and the Se atoms are all above the centers of the triangles formed by the fcc, hcp, and top sites (Fig. 1e); on Ag and Au(111), the W and Se atoms are all above the centers of the triangles formed by the fcc, hcp, and top sites (Fig. 1f). The most stable configurations of the BL WSe2–metal interfaces are similar to the corresponding ML ones. The equilibrium interfacial distances $d_i$ in ML and BL WSe2–metal contacts are insensitive to the WSe2 layer number, varying from 2.271 to 2.959 Å (Table 1). The binding energy per interfacial W atom is defined as

$$E_b = (E_{\text{WSe}_2} + E_{\text{metal}} - E_{\text{WSe}_2-\text{metal}})/N_W$$

where $E_{\text{WSe}_2}$, $E_{\text{metal}}$, and $E_{\text{WSe}_2-\text{metal}}$ are the relaxed energies for the WSe2 metal surface, and the combined system per supercell, respectively, and $N_W$ is the number of interface W atoms per supercell. $E_b$ ranges from 0.160 to 1.049 eV as listed in Table 1. Similar to the case of MoS2,21 the adsorption of ML and BL WSe2–metal surfaces can be classified into weak bonding (Al, Ag and Au contacts) with $E_b = 0.160–0.367$ eV, medium bonding (Pt and Pd) with $E_b = 0.525–0.706$ eV, and strong bonding (Sc) with $E_b = 0.918$ (ML) and 1.049 (BL) eV according to the binding strength.

It is important to note that the Schottky barrier may form at two possible interfaces in a transistor as shown in Fig. 1g: if the interaction between WSe2 and the metal surface is weak, it forms at the source/drain interface (B) between the contacted WSe2 and the metal surface in the vertical direction; otherwise, if the interaction between WSe2 and the metal surface is strong, it forms at the source/drain-channel interface (D) between the contacted WSe2 and channel WSe2 in the lateral direction. Such a dual interface model has been employed in the recent MoS2–graphdiyne– and ML phosphorene–metal contact studies.21,24,25,52 Compared with a single vertical interface model, which predicts an ohmic contact between ML MoS2 and Ti due to the strong band hybridization,29 the dual interface model predicts a Schottky contact with an electron SBH of 0.22–0.35 eV.21,24 A significant electron SBH of 0.30–0.35 eV between ML MoS2 and Ti is found experimentally,21 justifying the dual interface model. Actually, the calculated (0.096 eV) and observed (0.065 eV) electron SBH for BL MoS2–Ti is found consistent with the reported DFT-GGA,24,53 based on the dual interface model also show a good consistency.

Because SBH depends on the band edge positions of the semiconductor, the band edge positions of the semiconductor must be accurately determined. The DFT-GGA is a single electron theory and indeed underestimates the band gap of an intrinsic semiconductor, where many-body effects are non-negligible. The band gap and the CBM and VBM of an intrinsic semiconductor should be calculated by many-body Green’s function approach within the GW approximation. However, in a FET configuration, the semiconductor is either doped by a metal electrode or by a gate, and in this case, the electron–electron interaction is greatly screened by doped carriers, and single electron theory becomes a good approximation to the quasi-particle band gap and the band edge positions.24,26,54 Taking ML phosphorene as an example, the transport gap, quasi-particle band gap, optical gap, DFT-HSE (Heyd-Scuseria–Ernzerhof) band gap, and DFT-GGA band gap are 1.0,55 2.0–2.2,56,57 1.3–1.53,58 1.0–1.6,59–61 and 0.91 eV, respectively. The DFT-GGA band gap is a good approximation for the transport gap. This point is also proved by a comparison between the calculated and observed SBHs in 2D MoS2 devices. The experimentally extracted SBHs of ML and BL MoS2–Ti contact are 0.30–0.35 (ref. 21) and 0.065 eV,53 respectively, which are in agreement with the calculated values of 0.216 and 0.096 eV at the DFT-GGA level.24 Hence, the transport gap and the CBM and VBM of a semiconductor in a FET configuration can be approximately described by DFT-GGA, while the hybrid functional method and the quasi-particle method tend to overestimate the transport gap.

**SBHs and interface states**

The band structures of ML WSe2 and the combined systems are shown in Fig. 2. The ML WSe2 has a band gap of 1.60 eV when the SOC is absent, consistent with the reported DFT value of 1.67 eV.18 Both the valence and conduction bands of ML WSe2 are strongly destroyed when contacted with Sc, resulting in an absent vertical Schottky barrier for the ML WSe2–Sc contact. The majority of the ML WSe2 bands are still identifiable when in contact with Al, Ag and Au surfaces because of the weak interaction. When in contact with Pt and Pd surfaces, the valence bands of ML WSe2 are hybridized slightly with the d-bands of Pt and Pd, while the conduction bands are preserved well. Vertical Schottky barrier $\Phi_V$ for these weak or medium bonding cases (Fig. 1g) can be obtained from the energy difference between $E_F$ of the interfacial system and the CBM (electron SBH) or VBM (hole SBH) of the contacted WSe2. Strictly speaking, the terminology band is appropriate for homogeneous crystals, whereas for heterogeneous interfaces with orbital hybridization, the CBM/VBM of the semiconductor side can be identified by regarding the spilled hybridization states as interfacial gap states.26 As shown in Fig. 2, the WSe2 bands across the Fermi level with smaller weights originate from the band hybridization between WSe2 and metals. They can be regarded as a part of the interfacial gap states and won’t affect the SBH. Therefore, the band gap and CBM/VBM of WSe2 are determined through the projected WSe2 states at the $\Gamma$ point in the weak or medium bonding contacts. The band gap of ML WSe2 becomes 1.57, 1.62, 1.56, 1.15 and 1.51 eV in the ML WSe2–Al, –Ag, –Au, –Pd and –Pt contacts, respectively, which are generally smaller than that (1.60 eV) of the pristine WSe2 because of the broadening of the energy bands induced by the perturbation of metal electrodes. In ML WSe2–Al, –Ag and –Au contacts, as shown in Fig. 2, the vertical Schottky barriers are n-type with electron SBH of $\Phi_V = 0.70, \ldots$
0.50, and 0.66 eV, respectively. While in ML WSe₂–Pd and –Pt contacts, the vertical Schottky barriers are p-type with hole SBH of $\Phi_h^V = 0.22$ and 0.34 eV, respectively. The vertical electron/hole SBH in the ML WSe₂–Au/Pd contact (0.66/0.22 eV) is comparable with the one (0.70/0.35 eV) calculated by Banerjee et al. in the absence of the SOC effects. The nearly midgap SBH character of Al contact ($\Phi_e^V = 0.70$ eV and $\Phi_h^V = 0.87$ eV) is also consistent with the partial density of states (PDOS) calculations of Banerjee et al.

The band hybridization degree of the ML WSe₂–metal interfaces increases with the binding strength. The different bonding strength and band hybridization degrees in different interfaces can be well explained by the d-band model. Al has no d-orbitals and Ag and Au have full d-shells and they all bond with ML WSe₂ weakly, whereas Pt and Sc have open d-shells and bond with ML WSe₂ strongly. The relative position of the d-band also plays an important role. On moving from right to left in the periodic table, the d-band moves up in energy. Although Pt and Ag both have full 4d-shells, the d-band of Pd is located nearer to $E_F$ than that of Ag thus strongly hybridizes with the valence bands of WSe₂. The d-band of Sc is located near the conduction bands of ML WSe₂ in energy. Therefore, the conduction bands of ML WSe₂ are perturbed more seriously than its valence bands when in contact with Sc. Although the metal and W in WSe₂ are separated by a Se layer, their d-bands strongly hybridize with each other. Taking the ML WSe₂–Pt contact as an example, as shown in Fig. S1a, we can find a clear hybridization between Pt and W d-bands as their d-band dispersion curves coincide in some regions. The PDOS analysis shown in Fig. S1b further confirms this point as there is a big bump around $-1.2$ eV for both the Pt and W d-orbitals.

To further study the contact nature in the vertical direction, the PDOS of W and Se atoms in ML WSe₂–metal contacts are provided in Fig. 3. After contact with metal faces, there appear electronic states in the original band gap of ML WSe₂. The PDOSs at $E_F$ ($N(E_F)$) increases in this order: Au (0.39) < Al (0.50) < Ag (0.58) < Pt (1.08) < Pd (1.24) < Sc (2.1), a result consistent with the hybridization degree (for the Sc contact, we compare its $3N(E_F)$ value with the $N(E_F)$ of other metal contacts because its interface unit cell area is 1/3 of others). The prominent overlap between Sc and WSe₂ in the original band gap of WSe₂ indicates a covalent bond formation between them, thus further confirming the absence of the vertical Schottky barrier. In contrast, there are much fewer overlap interface states distributed in the original band gap for other contacts compared with those in the Sc contact. The overlap states near $E_F$ not only play an important role in the Fermi level pinning, but...
also contribute to the electron or hole injections from the metal to the semiconductor in terms of the mechanism proposed by Heine that the nature of these interface states originates from a decaying metallic wave function into the nanometer depth of semiconductors. Therefore, the PDOS value at $E_F$ can reflect the quality of vertical contacts to a degree. For example, the PDOS near $E_F$ in the ML WSe$_2$-Sc contact is rather large, and the vertical SBH vanishes in this contact.

The electronic structures of free-standing BL WSe$_2$ and BL WSe$_2$-metal interfaces are shown in Fig. 4, with a smaller indirect band gap of 1.43 eV for free-standing BL WSe$_2$. The band hybridization degree is similar to ML and can also be divided into the same three categories. The vertical Schottky barrier in the BL WSe$_2$-Sc system is also absent due to the strong hybridization between the bands of BL WSe$_2$ and Sc. The band gap of BL WSe$_2$ becomes 1.12, 1.12, 1.43, 1.19 and 1.25 eV in the BL WSe$_2$-Sc, -Al, -Ag, -Au, -Pd and -Pt contacts, respectively, which are also generally smaller than the value of the pristine one. In BL WSe$_2$-Sc, -Al, -Pd and -Pt contacts, the type of the vertical Schottky barrier is same as the ML case; the Schottky barriers are n-type with $\Phi_N^{\text{ff}} = 0.37$ and 0.30 eV in BL WSe$_2$-Al and -Ag, and are p-type with $\Phi_P^{\text{ff}} = 0.27$ and 0.32 eV in BL WSe$_2$-Pd and -Pt, respectively. In these four metal contacts, $\Phi_{\text{eff}}$ is decreased significantly in the n-type contacts while $\Phi_N^{\text{ff}}$ is not altered much in the p-type contacts compared with those in the cases of ML. The vertical Schottky barrier changes from weak n-type in ML WSe$_2$-Au contact to weak p-type with $\Phi_P^{\text{ff}} = 0.58$ eV in the BL case. In both cases, $E_F$ is close to the band gap center of WSe$_2$. Experimentally, ambipolarity is observed in few layer WSe$_2$ FET with an Au electrode, a result consistent with our calculation.

WSe$_2$ hosts heavy 5d elements with strong atomic SOC, much stronger than that in the more intensively studied MoS$_2$ system. After inclusion of the SOC effects, the band structures of ML and BL WSe$_2$ are greatly modified as shown in the first and second panels of Fig. 2 and 4 by lining up the bands with the vacuum level. The band gap of ML (BL) WSe$_2$ is reduced from 1.60(1.43) to 1.33(1.15) eV. The CBM of ML (BL) WSe$_2$ is changed slightly and only falls by 0.04 ($-$0.09) eV, but the VBM is significantly elevated by 0.23 (0.37) eV, after the SOC effects are included. Therefore, if the Fermi level pinning is absent during the SOC process, the electron vertical SBH is little affected, but the hole vertical SBH is decreased remarkably by about 0.23 (0.37) eV for the ML (BL) case once the SOC effects are included. As shown in Fig. 5, the CBMs of ML and BL WSe$_2$ are little changed (within 0.07 eV) in the Pd and Pt contacts. By contrast, the VBM of ML (BL) WSe$_2$ is lifted by 0.04 (0.18) eV in the ML (BL) WSe$_2$-Pd contact after inclusion of the SOC effect, and thus we have a reduced $\Phi_V^{\text{eff}} = 0.18$ (0.09) eV for hole injection. The VBM in the ML (BL) WSe$_2$-Pd contact is not elevated as high as in free-standing ML (BL) WSe$_2$, reflecting a partial Fermi level pinning during the SOC process. The reduction in $\Phi_V^{\text{eff}}$ is especially remarkable in the Pt contact. The VBM of WSe$_2$ touches $E_F$ in the ML and BL WSe$_2$-Pt contacts after inclusion of the SOC effects because of the significant rise of the VBM by about 0.34 and 0.32 eV, respectively, leading to ohmic or quasi-ohmic interfaces. The rise amplitudes of the VBM in ML and BL WSe$_2$-Pt contacts are comparable with those in free-standing ML and BL WSe$_2$, implying a much depressed or even vanishing Fermi level pinning during the SOC process in the Pt contact. The predicted p-type ohmic or quasi-ohmic contact for ML and BL WSe$_2$-Pt is in agreement with the very recent experimental results of Banerjee et al. that a dual-gated WSe$_2$ FET with Pt contacts has linear output characteristics in the low-voltage regime for all negative top biases even down to cryogenic temperature.

This indicates the importance of the SOC in determining the interfacial properties of the 2D WSe$_2$-metal contacts. We note that the band gaps of ML (BL) WSe$_2$ become 1.04 (1.07) and 1.10 (0.87) eV in the Pd and Pt contacts, respectively, which remain smaller than the value of 1.33 (1.15) eV in pristine WSe$_2$.

Because of the covalent bonding between WSe$_2$ and Sc, ML (BL) WSe$_2$-Sc can be regarded as a new metallic material. A lateral Schottky barrier is possibly formed at the interface D, and its height $\Phi_D^{\text{ff}}$ is determined by the energy difference between $E_F$ of the WSe$_2$-Sc complex system and the CBM (electron SBH) or VBM (hole SBH) of channel WSe$_2$. As has been discussed above, the transport gap of the 2D TMD channel could be determined by the DFT band gap rather than the quasi-particle band gap or the HSE band gap. As shown in Fig. S2,† lateral n-type Schottky barriers are formed for ML and BL WSe$_2$-Sc contacts with electron SBHs $\Phi_D^{\text{ff}(\text{Non-SOC})} = 0.29$ and 0.16 eV and $\Phi_D^{\text{ff}(\text{SOC})} = 0.25$ and 0.25 eV, respectively.
Fermi level pinning

The partial Fermi level pinning is a synergic result of the metal work function modification and the interface state formation in the studied interface systems. Fermi level pinning makes the contact nature complex and difficult to predict. The absolute band alignments between pristine ML/BL WSe₂ and metals are offered in Fig. S3. The differences between metal work functions and the CBM (VBM) of ML and BL WSe₂ are compared with the electron (hole) SBHs obtained by the energy band analysis of the interfacial systems in Fig. S3b and S3d, respectively. The discrepancy in the values shows that there exists a Fermi level pinning effect in the WSe₂–metal contacts. We define the Fermi energy shift \( \Delta E_f \) as

\[
\Delta E_f = \begin{cases} 
E_D - E_f, & \text{for vertical Schottky barrier} \\
W - W_{WSe_2}, & \text{for lateral Schottky barrier}
\end{cases}
\]

(3)

where \( E_D \) is the middle energy of the band gap of the WSe₂ adsorbed on metal substrates, \( E_f \) is the Fermi level of the interfacial system, \( W \) and \( W_{WSe_2} \) are the work functions of the combined system and pristine ML or BL WSe₂, respectively. Negative (positive) \( \Delta E_f \) means n-type (p-type) doping of WSe₂. \( \Delta E_f \) as a function of the difference between the clean metal and ML (BL) WSe₂ work functions \( W_M - W_{WSe_2} \) is shown in Fig. S4. We apply a linear fit to all the data obtained with or without the SOC effects. The slope is 0.40 in both ML and BL WSe₂–metal contacts, which is much smaller than the previously reported theoretical value of 0.64–0.71 in ML and BL MoS₂–metal contacts, indicating a higher degree of

Fig. 4 First panel: schematic illustration of the absolute band positions with respect to the vacuum level by the DFT method with and without inclusion of SOC effects for BL WSe₂. The remaining: band structures of BL WSe₂ and BL WSe₂–Sc, –Al, –Ag, –Au, –Pt, and –Pt contacts, respectively. Gray line: metal surface bands; red line: bands of WSe₂ without considering the SOC effects. The line width is proportional to the weight. Green line: bands of WSe₂ with the SOC effects. The Fermi level is set at zero.

Fig. 5 Band structures of (a, b) ML and (c, d) BL WSe₂ on (a, c) Pd, and (b, d) Pt surfaces with the SOC effects, respectively. Gray line: metal surface bands; red line: bands of WSe₂. The line width is proportional to the weight. The Fermi level is set at zero.
interface Fermi-level pinning in the WSe$_2$ contacts. The slope close to 1 means no Fermi level pinning and close to 0 indicates a strong Fermi level pinning. We therefore observe a partial Fermi level pinning picture in the six ML (BL) WSe$_2$–metal contacts.

Tunneling barrier

The tunneling barrier is another figure of merit to evaluate a contact, here its height $\Delta V$ defined as the potential energy above $E_f$ between the WSe$_2$ and metal surfaces, indicated by the blue rectangle in Fig. 6, and its width $w_B$ defined as the full width at half maximum of the $\Delta V$. In some metal contact studies, the barrier height is defined as the difference between the potential energy at the top metal layer and the maximum of the potential between the interfaces. The barrier height in our definition presents the lowest barrier that the electrons at $E_f$ need to overcome when injected from metal to TMDs, while in another definition, the barrier height means the highest barrier that the electrons need to overcome for injection. From a physical point of view, our definition more makes sense. As shown in Fig. 6 and Table 2, the weak bonding (Al, Ag and Au) and medium bonding (Pd and Pt) interfaces have a notably high $\Delta V$ and a notably wide $w_B$. In contrast, there is no tunneling barrier at the strong bonding interfaces (Sc), indicating a higher electron injection efficiency and thus a lower contact resistance. We estimate the tunneling probabilities $T_B$ from metal to WSe$_2$ using a square potential barrier model as:

$$T_B = \exp \left( -2 \times \frac{\sqrt{2m\Delta V}}{\hbar} \times \omega_B \right)$$  

where $m$ is the effective mass of a free electron and $\hbar$ is the Plank’s constant. The $T_B$ values are thus estimated to be 100 (100), 26.9 (47.9), 39.9 (52.2), 34.3 (42.7), 52.4 (78.8) and 31.0 (41.0)% for the ML (BL) WSe$_2$–Sc, Al, Ag, Au, Pd and Pt contacts, respectively. The tunneling probability is generally larger in the BL contact cases than the corresponding ML one. Apparently, Sc contacts have a perfect tunneling transmission. As discussed before, the PDOS value near $E_f$ can reflect the quality of vertical contacts to a degree. The ML WSe$_2$–Pt, –Pd and –Sc contacts have larger PDOS values near $E_f$. Consistently, the tunneling probabilities in them are generally larger than those in other metal contacts.

Quantum transport simulation

A more direct and reliable approach to determine the SBH of a 2D WSe$_2$ transistor is the ab initio quantum transport simulation. As an example, in Fig. 7, we present the simulated transport properties of the ML WSe$_2$ transistor with Pt electrodes (the SOC is not included). The length of the channel is 73 Å. From the transmission spectrum shown in Fig. 7b, we can see a transport gap of 1.65 eV and a hole SBH of 0.34 eV. From the local density of states plotted in Fig. 7c, a band gap of ~1.8 eV in the free ML WSe$_2$ region (dark blue) and a hole SBH of ~0.35 eV are clearly visible, comparable with the corresponding values derived from the transmission spectrum. The band bending of the free ML WSe$_2$ near the interface is not sharp, showing a weak built-in electric field between the source/drain and channel region. The SBH calculated in the...
transport simulation (0.34–0.35 eV) is consistent with that (0.34 eV) calculated from the energy band analysis without inclusion of the SOC.

This good agreement indicates that the energy band calculation is suitable in describing the vertical SBH in the weak and medium bonding contacts although it often gives an artificial vanishing lateral SBH in the strong bonding contacts. The reason lies in that in the vertical SBH calculation of a weak bonding contact, the coupling between the metal surface and the semiconductor is taken into account where the two parts are treated as a whole, but in the lateral SBH calculation of a strong bonding contact, the coupling between the source/drain region (metal and metal contacted 2D semiconductor) and the channel semiconductor is not considered where they are treated separately. Since WSe₂–Pt belongs to the medium bonding contact, we therefore believe that the ohmic or quasi-ohmic feature of ML/BL WSe₂–Pt contacts should be kept in a quantum transport simulation with inclusion of the SOC though it is unavailable now.

To provide a clear picture, the SBHs obtained by different methods are summarized in Fig. 8. When in contact with the same metal, compared with those in the ML case, the electron and hole SBHs in the BL case both tend to be decreased due to the much reduced band gap. From left to right, the ML and BL WSe₂ are gradually changed from n- to p-type doping, which can be utilized to build p–n junctions, the most fundamental device building blocks for diverse optoelectronic functions. A ML WSe₂ device with Ti as the cathode and Pd as the anode is synthesized and can serve as a solar cell, photodiode, and light-emitting diode with impressive performances. P-type ML WSe₂–Pd contact has a smaller SBH compared with the Ag and Au contacts, which is well consistent with the contact resistance measurement. In the absence of the SOC, the Pd contact has the smallest hole SBH with a value no less than 0.22 eV though Pd has a larger work function than Pt (5.76 eV vs. 5.36 eV in our work as given in Table 1). However, the Pt contact wins the smallest hole SBH (actually 0 eV) in the presence of the SOC.

Note that the p-type WSe₂ FET in contact with the metal Pt/Au/Pd electrode reported by Javey et al. has a large contact resistance of about 1 MΩ·μm, whereas another experiment confirms our prediction of the ohmic WSe₂–Pt contact. The inconsistency in these two reports may result from the different fabrication processes and experimental conditions. In ref. 6, a Pt/Au/Pd (10/30/20 nm) metal stack is directly deposited on WSe₂ as a top-contact, whereas in ref. 65, the WSe₂ is stamped onto the prepatterned Cr/Pt electrodes. There also exist some discrepancies between computational simulation and experimental results. Banerjee et al. claimed that the contacts between ML MSe₂ and Ti, In, and Ag are n-type ohmic in terms of their observed linear output characteristics. However, in our opinion from the observed larger contact resistance and lower two-terminal field-effect mobility in the Ti contact compared with In and Ag contacts, the Ti contact appears not ohmic. Nearly linear Ids – Vds characteristics in the low-voltage regime can be attributed to thermally assisted tunneling through a Schottky barrier at room temperature. The simulation study done by the same group revealed that Ti and In form n-type Schottky barriers to ML WSe₂ with heights of

Fig. 7  Simulation of a ML WSe₂ transistor with Pt as electrodes without inclusion of the SOC. (a) Schematic configuration. (b) Zero-bias transmission spectrum. The transport gap and hole SBH are indicated. (c) Local density of states (LDOS) in color coding for the device. 0.33 and 0.47 eV, respectively. And our calculations show that Ag forms a n-type Schottky contact to ML WSe₂. The reasons for these contradicting results may lie in that the TMD–metal interface is highly sensitive to the experimental processing environment such as vacuum conditions in the deposition chamber, deposition rate, and metal topography.

In light of the Schottky barrier and tunneling barrier, the nature of the investigated ML WSe₂–metal contacts can be classified into four types as summarized in Fig. 9. ML WSe₂–Sc contact is type I with a vanishing tunneling barrier and a finite n-type lateral Schottky barrier (Fig. 9a). A non-zero tunneling barrier exists in the remaining three types of contacts. The
Schottky barrier is formed at the interface B in type II (n-type) and III (p-type). The nature of ML WSe$_2$–Al, –Ag and –Au belongs to type II (Fig. 9b) and that of ML WSe$_2$–Pd belongs to type III (Fig. 9c). Type IV (ML WSe$_2$–Pt) can be expected as an excellent contact interface with an ohmic or quasi-ohmic contact (Fig. 9d). However, the tunneling barrier with moderate tunneling probabilities (31.0% for Pt) would degrade its performance. As for BL WSe$_2$, BL WSe$_2$–Sc, Al, Ag, Pd and Pt interfaces keep the same contact type as the corresponding ML ones. However, WSe$_2$–Au changes into type III contact in the BL case. It should be stressed that the band bending direction is opposite in the 2D semiconductor–metal and the corresponding n- or p-type conventional bulk semiconductor–metal blocking contacts (Fig. S5†). The band of 2D semiconductors is bent upward in the p-type contact and bent downward in the n-type contact when approaching the metal.

It has been pointed out that the actual transport gap of the channel, which could be described by the DFT band gap as a good approximation, equals the quasi-particle band gap of the heavily doped semiconductor. Therefore, a small correction to the DFT gap may be needed [an increase by about 10%]. An increase by about 10% in the band gap of ML/BL WSe$_2$ with the SOC effects implies a decrease and increase of about 0.06 eV in the VBM and CBM, respectively [half band gap correction], and such a correction may lead to a small correction to the SBH (less than 0.06 eV in light of the Fermi level pinning effect).

When different facets of metals are in contact with the same 2D materials, the SBH may usually be different, because the different facets of metals reveal facet-dependent surface energies, surface states and work functions thus leading to different contact behaviors. For example, the calculated hole SBH in the phosphorene–Ti (0001) contact is 0.30 eV, while in the phosphorene–Ti (1100) contact it is 0.57 eV. Therefore, the SBH would change if WSe$_2$ is in contact with other facet surfaces instead of (111) in fcc and (0001) in the hcp metals studied in this work.

**Conclusions**

We provide the first comparative study of the interfacial properties of ML and BL WSe$_2$ on Sc, Al, Ag, Au, Pd, and Pt surfaces by using ab initio energy band calculations with inclusion of the SOC effects and a dual interface model. Compared with ML WSe$_2$–metal contacts, the electron and hole SBHs are decreased in the BL WSe$_2$–metal contacts due to the smaller band gap in BL WSe$_2$, and the polarity of the WSe$_2$–Au contact changes from n-type to p-type. The hole SBH is greatly reduced by the SOC effects in both ML and BL WSe$_2$–metal contacts. In the absence of the SOC, Pd contact has the smallest hole SBH with a value no less than 0.22 eV. Dramatically, p-type ohmic or quasi-ohmic contact appears in ML and BL WSe$_2$–Pt interfaces with inclusion of the SOC. Ab initio quantum transport simulation gives a similar SBH for the ML WSe$_2$–Pt interface in the absence of the SOC. This fundamental study gives a deep insight into 2D WSe$_2$–metal interfaces and provides a theoretical foundation for the selection of metal electrodes in WSe$_2$ devices.
