Abstract. In solar wind, dissipation of slow-mode magnetosonic waves may play a significant role in heating the solar wind, and these modes contribute essentially to the solar wind compressible turbulence. Most previous identifications of slow waves utilized the characteristic negative correlation between $\delta |B|$ and $\delta \rho$. However, that criterion does not well identify quasi-parallel slow waves, for which $\delta |B|$ is negligible compared to $\delta \rho$. Here we present a new method of identification, which will be used in 3-D compressible simulation. It is based on two criteria: (1) that $V_{\parallel}B_0$ (phase speed projected along $B_0$) is around $\pm c_s$, and that (2) there exists a clear correlation of $\delta v_{\parallel}$ and $\delta \rho$. Our research demonstrates that if $v_A > c_s$, slow waves possess correlation between $\delta v_{\parallel}$ and $\delta \rho$, with $\delta \rho/\delta v_{\parallel} \approx \pm \rho_0/c_s$. This method helps us to distinguish slow-mode waves from fast and Alfvén waves, both of which do not have this polarity relation. The criteria are insensitive to the propagation angle $\theta_{kB}$, defined as the angle between wave vector $k$ and $B_0$; they can be applied with a wide range of $\beta$ if only $v_A > c_s$. In our numerical simulation, we have identified four cases of slow wave trains with this method. The slow wave trains seem to deform, probably caused by interaction with other waves; as a result, fast or Alfvén waves may be produced during the interaction and seem to propagate bidirectionally away. Our identification and analysis of the wave trains provide useful methods for investigations of compressible turbulence in the solar wind or in similar environments, and will thus deepen understandings of slow waves in the turbulence.

Keywords. Interplanetary physics (MHD waves and turbulence)
and dimensionless cross-helicity $\sigma_c$. However, these criteria require a wave train with a pure mode, and may fail when waves of different modes mix up. Though cases reported by Y13 did agree well with this requirement, the usability of these criteria is limited. (Various linear spectral models (e.g., Klein et al., 2012) can be used for the problem.)

Recently simulations of these wave modes in MHD turbulence have been carried out. Simulations of compressible turbulence are especially important in that they promote our understandings of wave features and wave–wave interactions in the solar wind turbulence. To our knowledge, most of them focus on the statistical properties of compressible modes regarded as components of MHD turbulence. Most relevant research and reviews – e.g., Cho et al. (2002), Cho and Lazarian (2003, 2005), Vestuto et al. (2003), Brunt and Mac Low (2004), Elmegreen and Scalo (2004), Zhou et al. (2004), Hnat et al. (2005), Kowal et al. (2007), Shivamoggi (2008), Kowal and Lazarian (2010), Tofflemire et al. (2011), and Brandenburg and Lazarian (2013) – have concentrated on spectral properties and/or anisotropy of different MHD wave modes. Among these, Hnat et al. (2005), Shivamoggi (2008), and Kowal and Lazarian (2010) focused on compressible modes and investigated their characteristics. There was also research investigating the correlations of quantities in turbulences as well as dominating modes in of MHD turbulences. Passot and Vazquez-Semadeni (2003) have found that which wave mode dominates the contribution to density fluctuations in turbulences is decided by $\theta_{kB}$ and Alfvénic Mach numbers $M_A$. When $M_A$ is low, the slow mode is more dominant, especially when $\theta_{kB}$ is close to 90°. Wisniewski et al. (2013) researched the ratio of energy of different modes as well as anisotropy. However, the local behaviors of MHD waves are seldom discussed.

Among these, it is worth highlighting the works of Cho et al. (2002) and Cho and Lazarian (2003, 2005). Those studies mainly covered the anisotropy of MHD waves turbulence spectra, but also extended their discussion to include the generation of fast/slow waves in ambient Alfvénic fluctuations. It was shown that fast/slow waves can be generated in pure Alfvén wave background (explicitly reported by Cho and Lazarian, 2005), but these articles did not include direct identifications of the generated MHD waves. Instead, only global, statistical parameters were extracted using a “projection” method. In order to “decompose” wave modes, complex amplitudes $\delta \psi(k)$ were projected on eigenvectors determined by the background magnetic field $B_0$ and wave vector $k$. The Alfvén mode has velocity oscillations in the $B_0 \times k$ direction, while the fast mode oscillates quasi-perpendiculary and slow mode the in quasi-parallel direction, both in the plane in which both $B_0$ and $k$ lie.

In this article we intend to identify slow wave trains from our simulations of MHD turbulences and describing their evolution and possible interaction with other types of MHD waves. Our goal differs from previous studies in that we provide direct and descriptive examples of slow waves, focusing on local behaviors and deformation of the associated wave trains. Our criteria are insensitive to $\theta_{kB}$ and more versatile than the correlation between $\delta \rho$ and $\delta B_1$.

In Sect. 2 we introduce our numerical model. In Sect. 3 we give a brief prescription of the identification of MHD waves and verify our new methods. In Sect. 4 we present our slow wave cases and compare them with the case of Y13. Finally, in Sect. 5 we summarize the results and present some discussions.

### 2 Model description

In this section, we briefly introduce the codes that we used in our compressible turbulence simulation. We have conducted an MHD simulation with codes employing a splitting-based finite-volume scheme (Feng et al., 2011; Zhang et al., 2011; Yang et al., 2013), where the magnetic field is computed with the constrained transport (CT) algorithm (Tóth, 2000) and the fluid part with a Godunov-type central scheme (Ziegler, 2004; Fuchs et al., 2009). The codes are based on the PARAMESH package (MacNeice et al., 2000) and provide compressible solutions. (See Fig. 1.) The model is defined in a three-dimensional rectangular coordinate system, with $256 \times 256 \times 256$ grid points along the $x$, $y$, and $z$ directions, respectively. The corresponding computational region ranges from 0 to 2π in each direction. The model describes an ideal MHD system whose adiabatic index $\gamma = 5/3$, without explicit kinetic or magnetic viscosity terms.

All data and analyses presented in this article make use of a dimensionless unit system to simplify and clarify the illustration of the method. However, in order to interpret physical significances, a set of conversion factors should be set. In the solar wind at 1 AU, the typical Alfvén speed is about $100 \text{ km} \text{s}^{-1}$, and we denote it as 2 dimensionless velocity units. Hence the speed unit is $v_0 = 50 \text{ km} \text{s}^{-1}$. Typical solar wind contains about 5 protons per cubic centime-
ter, and so we assign the mass density unit to be $\rho_0 = 8 \times 10^{-21}$ kg m$^{-3}$. Their combination gives a unit of magnetic field $B_0 = 5.013$ nT. Take a period of $t_0 = 20$ s and the corresponding length is $L_0 = 1$ Mm.

A simulation of decaying turbulence is performed. As initial conditions, we adopt random “broadband initial conditions” of Mattheaus et al. (1996). These initial conditions consist of a randomly superposed wave packet of velocity fluctuations $u(k)$ with $|u(k)|^2 \propto 1/(1 + (k/k_{\text{knee}})^2)$ in the $k$ range of $1 < k < 8$, where $k_{\text{knee}}$ is chosen to be 3. The parameter $q$ decides the slope of the initial turbulence spectrum. For oscillations we set $\langle v^2 \rangle = 0.5$ and $\langle v^2 \parallel \rangle = 0.5$, as well as $\langle \delta v \parallel \rangle = 0$. There are no oscillations of $v_z$ and $B$. We uniformly set the mass density $\rho_0 = 1$, temperature $T_0 = 0.6$, and magnetic field strength $B_0 = 2$. $B_{x0} = B_{z0} = 0$ in initial conditions, so that the initial Alfvén velocity ($v_A = B_0/\sqrt{\rho_0}$, in dimensionless unit system) is 2, and the speed of sound ($c_s = \sqrt{\gamma \rho_0/\rho_0}$) is 1. Hence, the plasma $\beta = 0.3$ everywhere. These initial conditions intend to simulate the solar wind with in situ compressible turbulence and represent the local solar wind observations, yet they do not reflect radial expansion nor large-scale shear or stream interactions (Mattheaus et al., 1996). Hence, the simulation is limited to describing the local behaviors and cannot describe large-scale phenomena, such as the radial evolution of solar wind turbulence.

We employ periodic boundary conditions on all six boundaries, considering the two following issues. Firstly, there is no rigid wall in the solar wind environment that our model simulates. Secondly, periodic boundary conditions correspond to wave modes propagating in an infinite space, so that the wave vector $k$, which stems from Fourier analysis, makes sense.

### 3 Wave mode diagnostics

In this section we present our methods to identify slow wave trains in the simulation data. The identification is mainly accomplished with help of time–space slices along $B_0$. We show that the slow wave trains exhibit a strong correlation between $\delta \rho$ and $\delta v_{\parallel}$, and such correlated structures propagate at a characteristic velocity. The theoretically predicted ratio $|\delta \rho/\delta v_{\parallel}|$ changes little with varying $\theta_{kB}$, and thus the determination of the wave vectors can be bypassed. Though we fix on a single $\beta$ in the test case, these criteria are quite credible whenever $v_A$ is quite above $c_s$.

In Sect. 3.1, we describe the methods to identify slow waves, and we show the necessary features of other modes as well. The identification mainly involves the dispersion relation and polarity relations, where the angle $\theta_{kB}$ functions as a kernel parameter, yet the results are insensitive to it. In Sect. 3.2, we justify our method and check its robustness and applicability. We use a randomly generated wave packet to verify the correlation of $\delta \rho(t)$ and $\delta v_{\parallel}(t)$. The correlation only depends on the sign of $\cos \theta_{kB}$, regardless of the absolute value of $\cos \theta_{kB}$. The justification ensures that the method is reliable and available for analysis of time series.

#### 3.1 Identification and features of MHD waves

Firstly, it is worth revisiting theoretical solutions of MHD waves, i.e., dispersion and polarity relations. These results are built on two hypotheses: (i) linearized oscillations, i.e., fluctuations, are small enough that higher order terms can be neglected, and (ii) there is only one monochromatic plane wave of one mode. With these hypotheses one can decompose a physical quantity $\psi$ into a constant “background” part and an oscillating part:

$$\psi(x, t) = \psi_0 + \text{Re}(\delta \psi \exp(i(k \cdot x - \omega t)),$$  

where the background $\psi_0$ and the complex amplitude $\delta \psi$ are constant. When only the oscillating part is discussed we will simply use $\delta \psi$ instead.

Single-fluid MHD equations can only support three modes of waves: fast, slow, and Alfvén mode. If the speed of sound $c_s$, Alfvén speed $v_A$, and $\theta_{kB}$ are given, the phase velocities of fast and slow modes are determined according to

$$V_{p,\pm} = \frac{\sqrt{c_s^2 + v_A^2 \pm \sqrt{(c_s^2 + v_A^2)^2 - 4c_s^2v_A^2\cos^2\theta_{kB}}}}{2},$$

where the plus sign is for fast waves and minus for slow waves. The dispersion relation simply reads $\omega = V_p k$.

For fast and slow mode, polarity relations in the form given by, for example, Olbers and Richter (1973) and Marsch (1986) are presented here (with some symbols altered and unit system changed so that the permeability of free space $\mu_0$ is 1):

$$\delta \hat{\rho} = \epsilon \rho_0,$$  

$$\delta \hat{\mathbf{v}} = \epsilon \cdot \frac{V_p}{V_p^2 - v_A^2 \cos^2 \theta_{kB}} (V_p^2 \hat{\mathbf{k}} - v_A^2 \cos \theta_{kB} \hat{\mathbf{B}}),$$  

$$\delta \hat{\mathbf{B}} = \epsilon \cdot \frac{V_p v_A}{V_p^2 - v_A^2 \cos^2 \theta_{kB}} \cdot (\hat{\mathbf{B}} - \cos \theta_{kB} \hat{\mathbf{k}}) \sqrt{\rho_0},$$

where $\epsilon$ is the relative density fluctuation amplitude. Here it is plausible to omit the expression of $\delta \hat{\rho}_{th}$ from the solutions, since it is merely a passive quantity directly related to $\delta \hat{\rho}$ (e.g., Zank and Mattheaus, 1993). From the form, it is worth noting that both $\delta \hat{\mathbf{v}}$ and $\delta \hat{\mathbf{B}}$ lie in the plane defined by $B_0$ and $\hat{\mathbf{k}}$ (e.g., take $B_0 = (0, 0, B_0)$ and $\hat{\mathbf{k}} = (k_x, 0, k_z)$, and the fluctuations will lie in the $x$–$z$ plane). In that plane the parallel and perpendicular directions can be defined relative to $B_0$. From Eq. (3b) the parallel and perpendicular components of

---

www.ann-geophys.net/33/13/2015/

Where the plus sign corresponds to the case \( k_\parallel > 0 \), and vice versa for the minus sign. The Alfvén wave has \( \delta \hat{B} = \delta \hat{\rho} = 0 \).

Its velocity and magnetic field oscillate in \( \mathbf{k} \times \mathbf{B}_0 \) direction, with

\[
\delta \mathbf{v} = \pm \frac{\mathbf{B}_0}{\sqrt{\rho_0}}.
\]

with the minus sign for \( k_\parallel > 0 \) and vice versa for \( k_\parallel < 0 \).

Let the phase velocity of the wave be \( V_p \) and the propagation velocity of wave phase along \( \mathbf{B}_0 \) be \( V_{pc} \). Then, since \( V = \omega/k \),

\[
V_{pc} = \frac{\omega}{k_c} = \frac{\omega}{k \cos \theta_{kB}} = \frac{V_p}{\cos \theta_{kB}}.
\]

Since \( V_{pc} \) depends only on \( \theta_{kB} \) instead of \( \omega \), Eq. (7) also applies for wave packets with all components sharing the same \( \theta_{kB} \). For fast, slow, and Alfvén modes we plot \( V_{pc} \) versus \( \theta_{kB} \) in Fig. 2a. Along \( \mathbf{B}_0 \), Alfvén mode travels at a speed of 2, independent of \( \theta_{kB} \). For fast mode, \( |V_{pc}| \) is greater than or equal to 2, more approximated to 2 at smaller \( \theta_{kB} \). For slow mode, \( |V_{pc}| \) does not vary much from 1. As a result, slow mode structures stand out due to the distinguishing velocity along \( \mathbf{B}_0 \), and the analysis of phase-propagating speed \( |V_{pc}| \) still works for general wave packets.

Next we analyze characteristic velocity oscillations of fast and slow waves. Since the wave energy density can be calculated as \( \rho \left( \delta \mathbf{v} \right)^2 \), the amplitudes of \( \delta \mathbf{v} \) can represent wave energy. In our case \( v_A = 2 \) and \( c_s = 1 \), and from Eqs. (4a) and (4b) the inequality \( |\delta v_\perp/\delta v_\parallel| < 0.12 \) is valid, i.e., the oscillations of slow waves keep within 7° (i.e., arctan 0.12) relative to \( B_0 \) (see Fig. 3). Oscillations in parallel direction thus contribute at least 98% to the wave energy (because this percentage \( \rho_0 \delta v_\parallel^2/(\rho_0 \delta v^2) \) can be written as \( 1/(1 + \delta v_\perp^2/\delta v_\parallel^2) \), which is greater than \( 1/(1 + 0.12^2) \approx 0.986 \)). For fast mode, one can infer in the same fashion that the perpendicular direction contains almost all of the wave energy. Therefore, it is suitable to assign the parallel direction as the characteristic direction of velocity oscillations of slow mode, and the perpendicular one for the fast mode.

From Eqs. (3a), (4a) and (4b), one can derive that

\[
\frac{\delta \hat{\rho}}{\delta \hat{v}_\perp} = \frac{\rho_0 \cdot (V^2 - \cos^2 \theta_{kB} V_A^2)}{V \cdot (V^2 - v_A^2)} \cos \theta_{kB},
\]

\[
\frac{\delta \hat{\rho}}{\delta \hat{v}_\parallel} = \frac{\rho_0 \cdot (V^2 - \cos^2 \theta_{kB} V_A^2)}{V^3 \sin \theta_{kB}} \cos \theta_{kB}.
\]

Considering the characteristic velocity oscillation above, we take the former equation for the analysis of slow wave and the latter of fast wave. Figure 2b clearly presents \( \delta \hat{\rho} / \delta \hat{v}_\perp \).
of fast mode and $\delta \rho / \delta v_{||}$ of slow mode. For slow mode, the polarity of $\delta \rho / \delta v_{||}$ depends on the signs of $k_{||}$, and the ratio is not sensitive to $\theta_{kB}$ in each branch. In our case with $v_A > c_s$, maximal compression per unit “characteristic oscillation” occurs when $\theta_{kB} = 0$ or 180°, where $|\delta \rho / \delta v_{||}| = \rho_0 / |V(\theta_{kB} = 0)| = \rho_0 / c_s$. The minimum occurs as $\theta_{kB} \to 90°$, with $|\delta \rho / \delta v_{||}| \to v_A \rho_0 / (c_s \sqrt{v_A^2 + c_s^2})$. The ratio of the minimum to the maximum of $|\delta \rho / \delta v_{||}|$ is $v_A / \sqrt{v_A^2 + c_s^2}$ (in our case $\approx 0.894$). If $v_A$ is much larger than $c_s$, it is safe to assume

$$|\delta \rho / \delta v_{||}| \approx \frac{\rho_0}{c_s}.$$  

(9)

For fast mode, when $\theta_{kB}$ is near 0 or 180°, there is no obvious compression, but when $\theta_{kB}$ is close to 90°, the ratio (Eq. 8b) approaches $\rho_0 / \sqrt{v_A^2 + c_s^2}$.

As above, the diagnosis of slow wave utilizes two criteria: wave phase speed along $B_0$ and $\delta \rho / \delta v_{||}$. The criteria work well in cases with $v_A > c_s$, yet better when the ratio $v_A / c_s$ is greater (i.e., with smaller $\beta$), where all the approximations applied here will be slightly more precise. In order to employ them in data analysis, we must derive a relation between $\delta \rho(t)$ and $\delta v_{||}(t)$. In other words, we should further justify that

$$\frac{\delta \rho(t)}{\delta v_{||}(t)} \approx \pm \frac{\rho_0}{c_s}$$  

(10)

also holds well. The plus sign is for wave packets consisting of slow wave with $k_{||} > 0$, and the minus sign for $k_{||} < 0$.

We also compute

$$\sigma_c(x,t) = \frac{2 \langle \delta v \cdot \delta b \rangle}{|\delta v \cdot \delta v_{||} + (\delta b \cdot \delta b)|},$$  

(11a)

$$C_p(x,t) = \frac{\langle \delta \rho^2 \rangle}{\rho_0^2} \frac{B_0^2}{\langle \delta B \cdot \delta B \rangle}.$$  

(11b)

The quantity $\delta b = \delta B / \sqrt{\rho_0}$ denotes fluctuations of the magnetic fields, normalized to have velocity units. Gary and Winske (1992) pointed out that $\sigma_c$ and $C_p$ distinguish wave modes sharply: in our case, slow waves should have $C_p \gg 1$ and negative $\sigma_c$, Alfvén waves and “small-angled” fast waves should have $C_p \approx 0$ and $\sigma_c$ near to $-1$, and “large-angled” fast waves should have $C_p < 1$ and $\sigma_c$ between $-1$ and 0 (see Table 1, from Table 1a of Gary and Winske, 1992). These conclusions are for cases where $k \cdot B_0 > 0$. For cases where $k \cdot B_0 < 0$, $\sigma_c$ will change signs, and $C_p$ will remain unchanged. The computation of the two parameters is identical to that of Y13 (cf. Y13’s Eqs. 1 and 2).

In summary, MHD waves can be categorized into three types: (i) slow waves, (ii) Alfvén waves and quasi-parallel propagating fast waves (AW-like), and (iii) oblique and quasi-perpendicular propagating fast waves (fast-like). With $v_A = 2, c_s = 1$ and $\rho_0 = 1$ (typical for $\beta < 1$), their behaviors can be listed and compared in Table 1. For completeness, the non-propagating entropy mode is also supplied. This mode has inhomogeneity of density and temperature, but keeps pressure, velocity and magnetic field strength all uniform. Since quasi-parallel phase-propagating slow waves show little $\delta B$, it may be problematic to analyze correlations between $\delta \rho$ and $\delta B_{||}$ in such situations. However, since in the solar wind compressible fluctuations have larger $k_{\perp}$ than $k_{||}$ (Chen et al., 2012), such quasi-parallel cases may be neglected.

### 3.2 Justification of methods

The criteria described in Sect. 3.1 are based on the hypothesis that only a monochromatic wave of a given mode is involved. This is hardly the case in reality, where turbulent fluctuations have a wide range of frequencies and/or wave vectors, and different kinds of modes may be superposed.

To check the performances of the criteria in complicated cases, we have constructed a slow-mode wave packet to investigate the correlation of $\delta \rho$ and $\delta v_{||}$. The packet consists of $N$ wave modes, i.e., for $\delta \rho$ and $\delta v_{||}$

$$\delta v_{||}(x,t) = \sum_{i=1}^{N} \hat{v}_{||i} \exp(i(k_i \cdot x - \omega t)),$$  

(12a)

$$\delta \rho(x,t) = \sum_{i=1}^{N} \hat{\rho}_i \exp(i(k_i \cdot x - \omega t)).$$  

(12b)

For each mode $i$, we generate complex amplitude $\hat{v}_{||i}$ with random moduli and initial phase. Each wave mode has a random $k$, whose magnitude and direction are randomly decided with only one restriction $\theta_{kB} < 89°$. This is intend to guarantee that $k_{||}$ keeps the same sign in the wave packet. The corresponding $\omega$ is determined by $k$ from dispersion relation. Hence we can calculate $\hat{\rho}_i$ from $\hat{v}_{||i}$ with Eq. (8a), which describes the polarity relation between $\hat{\rho}$ and $\hat{v}_{||}$.

To test Eq. (10), we computed time profiles at the point $x = (0,0,0)$ of $\delta v_{||}$ and $\delta \rho$. The parameters are taken as in our initial condition: $v_A = 2, c_s = 1$, and $\rho_0 = 1$, so we expect the ratio to be about 1. For each of $N = 80$ modes, amplitudes of $\delta v_{||}$ are randomly selected in the range from 0 to 1, initial phase from 0 to $2\pi$, azimuthal angle of $k_{\perp}$ (relative to $B_0$) from 0 to $2\pi$, and $|k|$ from 0 to 2 in order to implement the random superposition of wave modes and extend the range of frequencies. The plots of $\delta v_{||}$ and $\delta \rho$ almost overlap in Fig. 4, which implies the ratio $\approx 1$. In this way the method is justified.

If other modes coexist, the correlation between $\delta \rho$ and $\delta v_{||}$ may be (or not) destroyed, depending on the type of the coexisting wave. Fast and Alfvén waves do not have obvious $\delta v_{||}$. As a result, observed $\delta v_{||}$ is contributed by slow waves. The correlation is possibly affected when the coexisting mode is either “large-angled” fast wave or slow wave propagating in the opposite direction. At the same time, however, whenever only Alfvén waves and/or parallel propagating fast waves coexist, the correlation will remain intact. To analyze mixed

Figure 4. Time profiles of $\delta v(t)$ and $\delta \rho(t)$ of a composed wave packet containing slow waves with random amplitudes, random wave vectors ($k_\parallel > 0$), and random initial phase. The vertical axis is for oscillating quantities, and the horizontal axis represents time $t$.

For case 1 (see the white lines in Fig. 1), profiles of characteristic quantities are plotted in Fig. 5. Red squares in panel a track the slow wave train. The points tracked are maxima of density $\rho$. Panel b plots a $z-t$ profile of $v_c$ with the same tracked points marked. Since slow waves usually appear shortly in turbulences, their widths are confined so that we can analyze the region near to the marked points. For each time $t$ with the wave peak marked at $z = z_p(t)$, we take the points where $z_p - 0.2 \leq z < z_p + 0.2$ and define them as “wave points”. An estimation of background quantities can be obtained from the average of all wave vectors ($k_\parallel > 0$) and random profiles of $d\delta v_c/dz$. With two secondary wave trains displayed.

4 Results

In this section we analyze the data from compressible simulations with the methods above and diagnose possible slow wave cases, four of which are presented with one in detail and the others in brief.

The data are extracted in time–space slices with coordinates $x$ and $y$ fixed, so that the slices lie in the $z$ direction. The primary characteristics of the cases are listed in the Table 2. Propagating speeds are computed by fitting the track of phase in the $(z,t)$ diagram. Averaged values and oscillations are evaluated with “wave points” (defined in the next paragraph).

For case 1 (see the white lines in Fig. 1), profiles of characteristic quantities are plotted in Fig. 5. Red squares in panel a track the slow wave train. The points tracked are maxima of density $\rho$. Panel b plots a $z-t$ profile of $v_c$ with the same tracked points marked. Since slow waves usually appear shortly in turbulences, their widths are confined so that we can analyze the region near to the marked points. For each time $t$ with the wave peak marked at $z = z_p(t)$, we take the points where $z_p - 0.2 \leq z < z_p + 0.2$ and define them as “wave points”. An estimation of background quantities can be obtained from the average of all wave points through the time span, giving $\tilde{B} \approx (-0.1, -0.5, 2.0)$ and $\tilde{v} \approx (-0.4, -0.3, 0.04)$ in $(x,y,z)$ coordinates. The angle between $\tilde{B}$ and $z$ axis is only $14^\circ$. In our qualitative analy-
sis it is reasonable to approximate the $z$ direction as the parallel direction. The background velocity $\bar{v}_z$ is not large enough to force the subtraction of this velocity from the wave speed along the $z$ slice. Meanwhile, $\bar{\rho}$ and $B_z$ change little from the initial condition, and thus the initial values are still valid as background values. The root-mean-square value of $\delta v_z$ is about 0.2, and $\delta \rho \approx 0.2$. This confirms to the polarity relations, and the root-mean-square values show that the wave train is linear in amplitude.

Panels a and b exhibit characteristic properties of a slow wave train: (1) an obvious density change ($\sim 20\%$), (2) typical propagating velocity $(1.04 \pm 0.049)$ around $c_s = 1$, and (3) good correlation between fluctuations of $\rho$ and $v_t$ (correlation coefficient $= 0.91$).

Equation (10) serves as another important criterion for slow-mode waves. To check against it, we have analyzed the correlation between $\delta v_z$ and $\delta \rho$ (Fig. 5d). As a reference, a blue line is plotted corresponding to $\delta \rho / \delta v_t = 1$. The points gather around the blue line, highlighting a typical strong correlation for slow waves. From the distribution the averages and oscillations are also calculated, so the averaged wave energy density can be calculated as $\bar{E}_w = \bar{\rho} (\delta v_z)^2$, and is listed in Table 2.

To explain Y13’s observation, we further compute some features employed in Y13’s analysis. We take points where $0 \leq z < 4.2$ on the slice at $t = 0.71$. The running smooth window used to compute $C_p$ and $\sigma_c$ has a width of 0.5, chosen as about a typical scale of the wave (see Fig. 5a). The results are presented in Fig. 6, where panels a and b are plotted without smoothing. Panel b shows the correlation of $v_z$ and $B_x$ as the result of searching for possible Alfvénic structures. Since the $x$ direction can be interpreted as a perpendicular direction, the Alfvén mode or small-angled fast mode both have $\delta v \approx \mp \delta B_x / \sqrt{\rho}$ (in the case of Alfvén waves, the equal sign holds strictly). In the segment marked with blue vertical lines in Fig. 6b, a negative correlation between $B_x$ and $v_z$ can be seen, and the amplitudes of their change are almost equal. In the same plot, the segment $z \leq 1$ shows almost overlapping profiles of $B_x$ and $v_z$. The two evidences may suggest an Alfvénic background. In this way, an Alfvén or small-angled fast-mode background is expected. For comparison with Gary and Winske (1992), panels c and d give parameters of the wave train. The wave points show $C \gg 1$ and $\sigma_c \approx -0.5$, which agrees well with the criteria. Therefore the slow-mode wave train is again identified.

Thus we identified a slow wave train embedded in Alfvénic-like structures, which explains Y13’s observation. However, the wave train does not propagate forever. This is also described in Fig. 5a and b. At $t = 0.87$, the density peak in panel a becomes hardly recognizable and starts to blur. At the same moment, the $v_z$ structure in panel b does not propagate any further. The slow wave train seems to be deformed. In Fig. 5a, a fan-like structure appears, hinting at a possible generation of at least two waves and propagation in oppo-

![Figure 6](https://example.com/figure6.png)
Figure 7. Temporal evolution of quantities along the \(x\) slice in case 1, taken to intersect the \(z\) slice in Fig. 5. (a) Temporal profiles of \(v_x\), with two wave trains displayed. (b) Temporal profiles of \(B_x\). (c) Temporal profiles of \(\rho\). (d) Distribution of \(\delta \rho\) and \(\delta v_x\) at points near the blue (left) wave train. (e) Distribution of \(\delta B_x\) (profile not plotted) and \(\delta v_x\) at points near the blue wave train. (f) Distribution of \(\delta B_x\) and \(\delta v_x\) at points near the cyan (right) wave train. In (d) to (f), the points are selected as ones within 0.1 unit length to the tracked points. Reddier markers stand for earlier time points and greener for later.

site directions. To check them, we plot \(dv_x/dz\) in panel c and marked in both wave trains in blue and cyan squares at local minima of the profile, respectively. These waves have the speed of fast waves, and moreover they cause density change. They are possibly “large-angled” fast waves.

To understand what happens to the wave train when it deforms, we take another slice along the \(x\) axis at the same time interval and with \(z = 2.3\) and \(y = 3.14\), so that it passes the site where the slow wave train begins to deform. We plot the corresponding profiles in Fig. 7, with maxima of \(|\partial v_x/\partial x|\) tracked, and we have them marked in panels a to c. The series of the maxima can be regarded as wave trains. The blue wave train exhibits some density fluctuations (see panel c), which are much smaller than in slow mode. To understand its wave mode, we perform two fits (see panels d and e). Its behaviors resemble fast waves with \(\theta_{KB} \sim 40^\circ\) (cf. Figs. 2a and 3). For the cyan wave train, the oscillations of \(B_x\) and \(v_x\) are similar (see panel b). A scatterplot of \(B_x\) and \(v_x\) near the cyan train is provided in panel f, displaying a positive correlation. The two trains are not slow waves, the blue one behaves “fast-like”, and the cyan one behaves somehow “Alfvén-like”. It is notable that they meet at \(z \approx 4.1\) and \(t = 0.87\), the very point where the slow wave train deforms.

Hence, the deforming of the slow wave train in case 1 can be described in such a scenario: a slow wave train interacts with at least two non-slow counterparts (one of them probably being “large-angled” fast waves), and deforms into at least two non-slow ones.

For other cases, only overviews of the slow wave trains are presented. In case 2 (Fig. 8), two slow wave trains propagate together. However, no clear wave form between the peaks is revealed. In contrast to case 1, the two waves remain quite a long time, especially for the wave train at larger \(z\) (case 2R). Moreover, waves in case 2 propagate “downwards” to smaller \(z\), while the counterpart in case 1 propagates “upwards” to larger \(z\). Accordingly, \(\delta \rho\) and \(\delta v|\) show negative correlation in case 2. Case 3 is a rather short case, whose profiles are shown in Fig. 9. Because we take fewer points along the wave train, the correlation coefficient \(r\) appears larger than that of cases 1 and 2. Before the slow wave train is formed, a fast wave train exists (see the cyan markers in panel c). At \(t \sim 0.47\), it seems to bifurcate, with most of its energy being transferred into the slow-mode train. A minor part continues propagating as fast or Alfvén mode, which is barely detectable in panel c after \(t = 0.47\). This scenario resembles the one discussed by Kudoh and Shibata (1999). After \(t = 0.67\), the slow wave train appears to excite another sharp wave train (panel c). However, the slow wave train does not fully deform. Case 4 is also a rather short case with pro-
files shown in Fig. 10. The excited wave is so weak that it can barely be detected (see panel c). However, the energy of
the deformed slow wave train may be contributed to the com-
plicated velocity structure shown at the top of Fig. 10b. In all
cases, the slow wave trains seem to be destroyed as they inter-
act with other modes at the same point. After the destruction,
new wave trains might be formed and shape “fan-like” struc-
tures shown in time–space slices of density. Such structures
are best shown in case 1, but still detectable in cases 2 to 4
(cf. Figs. 8a, 9a, and 10a).

5 Summary and discussions

This article establishes criteria to identify slow wave trains in
MHD simulation data, and presents four cases of such slow
wave trains. Several of their physical properties are extracted.
The main results are summarized here.

1. The identification of slow wave trains is achieved by
studying data along a slice approximately aligned to the
background magnetic field. Typical slow wave behav-
iors include $|V_{pc}| \approx \pm c_s$ and quite strong correlation of
$\delta \rho$ and $\delta v_{||}$, with their ratio $\sim \pm \rho_0/c_s$. They are consis-
tent with the derivation from dispersion and polarity re-
lations of linear MHD oscillations. These properties are
dominated only by the sign of $\cos \theta_{kB}$ and insensitive to
its absolute value, allowing us to bypass the calculation
of wave vector $\mathbf{k}$. The criteria are theoretically reliable
if $v_A$ is well above $c_s$, and they have passed a test with randomly generated wave packets.

2. Four cases of linear slow wave train are analyzed. They
comply well with the criteria. For case 1, the parameters
$\sigma_c$ and $C_p$ are computed, and they support the identifi-
cation.

3. Near the slow wave train of case 1, an Alfvénic structure
exists. This explains Y13’s observation as a local slow
wave train generated in an Alfvénic environment, ex-
cept that the existence of a pressure-balanced structure
cannot be clearly confirmed.

4. Such slow wave trains are inclined to dissolve. They de-
form suddenly, probably when they interact with other
waves, and their density structures will expand so that
they dissolve like a fan in time–space slice plots. The
boundary of the fan propagates at a typical speed of fast
wave, and the plasma there shares properties of the fast
wave or Alfvén wave. This is clearly shown by case 1,
but in other cases the fan-like density structures are also
detectable (though barely).

We have computed the wave energy density of the four
wave trains, and found that the wave energy densities are
about 0.03 to 0.04 except in case 2. All points in the com-
putational region at $t = 0.71$ give $\rho_0/\langle (\delta v)^2 \rangle \approx 0.39$. Since
the zones of compressible modes occupy a small portion of
the computational region, and energy densities of slow wave
trains are much smaller than the background fluctuations, it is
reasonable to roughly estimate the energy density of Alfvén
mode as 0.4. Since all four cases appear at time spans near
t = 0.71, this background energy density applies to all cases
in a rough estimation. Therefore, the typical wave energy
density of slow wave trains amounts about 0.1 in all fluc-
tuations. (For case 2, this proportion might be 0.2.)

There are certain limitations in this work. Firstly, this re-
search is limited within MHD descriptions. Kinetic mag-
etosonic waves behave differently from MHD eigenmodes
(Klein et al., 2012). Therefore, kinetic effects (not included
in our MHD investigation) may limit applications of the re-
ported MHD methods to solar wind observations. Slow mode
waves generally suffer more damping than Alfvén waves do.
Damping rates of slow modes vary with $\theta_{kR}$, with the quasi-perpendicular ones less damped (Barnes, 1966; Schekochihin et al., 2009). In the solar wind, the compressive fluctuations are found to be anisotropic with $k_\perp$ larger than $k_\parallel$, based on the structure function analysis (Chen et al., 2012). This explains why slow-mode fluctuations exist in the solar wind even though they suffer some damping. Nevertheless, our MHD model is limited in that it does not cover slow wave damping. Secondly, this work mainly focuses on phenomenal features of slow waves. However, their genesis has not yet been discussed, because our initial condition is a rather complex one and we need a method to trace the development of wave trains. With such a method, it would be possible to perform further investigations, such as analysis of fan structures in density profile, mechanisms of wave interactions, and relations between such wave trains and structures (e.g., discontinuities or intermittencies). Thirdly, though in principle our MHD model is limited in that it does not cover slow wave damping, this work mainly focuses on phenomenological features of slow waves. However, their genesis has not yet been discussed, because our initial condition is a rather complex one and we need a method to trace the development of wave trains. With such a method, it would be possible to perform further investigations, such as analysis of fan structures in density profile, mechanisms of wave interactions, and relations between such wave trains and structures (e.g., discontinuities or intermittencies). Thirdly, though in principle our numerical simulation is able to produce a time series of 3-D data, we are forced to select only the essential information for the analysis because of the formidable computational cost when high-resolution ($x, y, z, t$) data are produced and analyzed. Local analysis of such wave trains, which utilizes information about the three-dimensional and temporal evolution at local space-time points, may be conducted in future research. The analyses presented in this article employ slices and thus provide a workable compromise. Nevertheless, this research has to bypass some aspects such as determination of wave vectors, which may be essential for further analysis.
